(57) **ABSTRACT**

A compound optical circuit switches and methods are disclosed. Two or more 1st-tier switches may be coupled to one or more 2nd-tier switches. Each of a plurality of input ports may be connected to a respective input of one of the 1st-tier switches and each of a plurality of output ports may be connected to a respective output of one of the 1st-tier switches. Each connection between an input port and an output port connected to the same 1st-tier switch may be made within the 1st-tier switch. Each connection between an input port and an output port connected to two different 1st-tier switches is made along a respective connection path through the 1st-tier switch connected to the input port, through a selected 2nd-tier switch, and through the 1st-tier switch connect to the output port.

NOTICE OF COPYRIGHTS AND TRADE DRESS

A portion of the disclosure of this patent document contains material which is subject to copyright protection. This patent document may show and/or describe matter which is or may become trade dress of the owner. The copyright and trade dress owner has no objection to the facsimile reproduction by anyone of the patent disclosure as it appears in the Patent and Trademark Office patent files or records, but otherwise reserves all copyright and trade dress rights whatsoever.

BACKGROUND

1. Field

This disclosure relates to optical communications networks and more particularly to optical circuit switches using MEMS (micro-electromechanical system) mirror arrays.

2. Description of the Related Art

Communications networks commonly contain a mesh of transmission paths which intersect at hubs or nodes. At least some of the nodes may include a switching device that receives data or information arriving at the node and retransmits the information along appropriate outgoing paths.

Optical fiber links are commonly used to provide high bandwidth transmission paths between nodes. Such optical fiber links form the backbone of wide area networks such as the Internet. Optical fiber links are also applied in high bandwidth local area networks which may be used, for example, to connect server racks in large data centers or to connect processors in high performance computers.

An optical circuit switch is a switching device that forms connections between pairs of optical fiber communications paths. A typical optical circuit switch may have a plurality of ports and be capable of selectively connecting any port to any other port in pairs. Since an optical circuit switch does not convert information flowing over the optical fiber communication paths to electrical signals, the bandwidth of an optical circuit switch is essentially the same as the bandwidth of the optical communications paths. Further, since an optical circuit switch does not convert information into electrical signals, the power consumption of an optical circuit switch may be substantially lower than a comparable conventional (i.e. electronic) switch.

DESCRIPTION OF THE DRAWINGS

FIG. 1 is an optical schematic diagram of an optical circuit switch.

FIG. 2 is a block diagram of an environment for an optical circuit switch.

FIG. 3 is a block diagram of an optical circuit switch.

FIG. 4 is a block diagram of a compound optical circuit switch.

FIG. 5 is a block diagram of the compound optical circuit switch of FIG. 4 illustrating simple and compound connections.

FIG. 6 is a block diagram of another compound optical circuit switch.

FIG. 7 is a block diagram of another compound optical circuit switch.

FIG. 8 is a block diagram of another compound optical circuit switch.

FIG. 9 is a block diagram of another compound optical circuit switch.

2

FIG. 10 is a flow chart of a process for optimizing a connection through a compound optical circuit switch.

FIG. 11 is a flow chart of another process for optimizing a connection through a compound optical circuit switch.

FIG. 12 is a flow chart of a process for making a connection through a compound optical circuit switch.

FIG. 13 is a flow chart of another process for making a connection through a compound optical circuit switch.

FIG. 14 is a flow chart of a process for rebuilding connections through a compound optical circuit switch.

Throughout this description, elements appearing in figures are assigned three-digit reference designators, where the most significant digit is the figure number where the element is introduced and the two least significant digits are specific to the element. An element that is not described in conjunction with a figure may be presumed to have the same characteristics and function as a previously-described element having the same reference designator.

DETAILED DESCRIPTION

Description of Apparatus

Referring now to FIG. 1, an exemplary optical circuit switch **100** may be configured to connect a group of n inputs (where n is an integer greater than 1), labeled In 1 to In n , to a group of n outputs, labeled Out 1 to Out n . More specifically, the optical circuit switch **100** may selectively connect up to n pairs of inputs and outputs.

Each of the inputs In 1 to In n may include a connector (of which only the connector **110-1** is identified) to receive an input optical signal from an optical fiber cable (not shown) external to the optical circuit switch. Each connector may be coupled by a respective optical fiber (of which only optical fiber **112-1** is identified) to a respective tap coupler (of which only tap coupler **114-1** is identified). Each tap coupler may extract an input sample portion, for example 1% to 10%, of the input optical signal from the respective optical fiber. Each input sample portion may be directed to an input optical monitoring module **170**. The remainder of the input optical signals, other than the input sample portions, may be conveyed by respective optical fibers to respective collimator lenses (of which only collimator lens **118-1** is identified). Each collimator lens may convert the input optical signal from the respective optical fiber into a collimated input optical beam (of which only input optical beam **120-1** is identified) in free space. Free space optical beams are shown in FIG. 1 as dashed lines.

Each input optical beam, such as input optical beam **120-1**, may be directed onto a first mirror array **130**. The first mirror array **130** may include n mirrors with a one-to-one correspondence between input optical beams and mirrors, such that each input optical beam is directed onto a respective mirror. To improve the manufacturing yield of the first mirror array, the first mirror array **130** may include more than n mirrors, in which case the n input optical beams may be directed to a subset of n mirrors that are known to be fully functional. Since each of the n input optical beams originates from a specific port and is directed onto a specific mirror, each port may be described as "uniquely associated" with a corresponding mirror. In this patent, "uniquely associated" means a one-to-one correspondence. To take advantage of the available fully functional mirrors, the associations between ports and mirrors may be different in different optical circuit switches.

Each mirror on the first mirror array **130** may reflect the respective input optical beam to a selected mirror of a second mirror array **140**. The mirrors of the second mirror array **140**

may reflect the incident beam to form a respective output optical beam (of which only output optical beam **160-1** is identified). Each output optical beam may be directed to a corresponding focusing lens (of which only focusing lens **158-1** is identified). Each focusing lens may focus the respective output optical beam into an output optical signal in a respective optical fiber. Each output optical signal may be conveyed to a respective output tap coupler (of which only output tap coupler **154-1** is identified). Each output tap coupler may direct a sample portion (for example 1% to 10%) of the respective output optical signal to an output optical monitoring module **180**. The remainder of each output optical signal, other than the respective sample portion, may be conveyed to a respective output connector (of which only connector **150-1** is identified).

The input optical monitoring module **170** and the output optical monitoring module **180** may be a common module. The input optical monitoring module **170** and the output optical monitoring module **180** may measure the optical power in each of the input sample portions and output sample portions, respectively. Each of the input optical monitoring module **170** and the output optical monitoring module **180** may include an optical power detector for each sample portion. Alternatively, each of the input optical monitoring module **170** and the output optical monitoring module **180** may time-multiplex a single detector or an array of detectors such that each detector measures the optical power of sequence of sample portions. For example, each of the input optical monitoring module **170** and the output optical monitoring module **180** may use a scanning mirror to direct sample portions to a single detector or an array of detectors as described in U.S. Pat. No. 7,676,125.

Sample portions may be extracted from the input optical beams, such as input optical beam **120-1**, and/or the output optical beams, such as output optical beam **160-1**, using one or more free space sampling optical elements. For example, sample portions may be extracted as described in U.S. Pat. No. 6,597,825 or U.S. Pat. No. 6,668,118. Input tap couplers, such as input tap coupler **114-1** and/or output tap couplers, such as output tap coupler **154-1**, may not be present when free-space sampling optical elements are used to extract sample portions.

The optical circuit switch **100** may include a controller **190**. The controller **190** may control the mirror elements in the first mirror array **130** and the second mirror array **140** to make desired optical connections between the input In 1 to In n and the outputs Out 1 to Out n. For example, as shown in FIG. 1, input In 1 is connected to output Out 2, input In 2 is connected to output Out n, and input In n is connected to output Out 1. The controller **190** will be discussed in greater detail subsequently.

The detail view **115** shows a simplified schematic diagram of a mirror element from either the first mirror array **130** or the second mirror array **140**. A reflective mirror element **142** is supported by a pair of torsion bars, of which only a first torsion bar **144** is visible. The second torsion bar is located on the far side of the mirror element **142** and axially aligned with the first torsion bar **144**. The mirror element **142** may rotate about the axis of the torsions bars, with the torsion bars providing a spring force tending to return the mirror element **142** to a default position. The mirror element **142** may be coupled to a first electrode **146** and a second electrode **148**. The mirror element **142** may be rotated by electrostatic attraction between the mirror element and either the first electrode **146** or the second electrode **148**.

For example, applying a voltage between the first electrode **146** and the mirror element **142** will create an attraction

between the mirror element and the first electrode, causing the mirror element to rotate in a counter-clockwise direction. The mirror will rotate until the return force of the torsion bars is equal to the force of the electrostatic attraction. The angular rotation of the mirror element **142** may be approximately proportional to the square of the voltage between the first electrode **146** and the mirror element **142**. Similarly, applying a voltage between the second electrode **148** and the mirror element **142** will cause the mirror to rotate in a clockwise direction. The first electrode **146** and the second electrode may be “dedicated” to the mirror element **142**, which is to say the only function of the electrodes **146** and **148** is to rotate the mirror element **142** and the voltages applied to the electrodes **146** and **148** have no effect on any mirror element other than the mirror element **142**.

In the simplified example of FIG. 1, the mirror element **142** rotates about a single axis defined by the torsion bars **144**. Either or both of the first mirror array **130** and the second mirror array **140** may include mirrors configured to independently rotate about two orthogonal axes. In this case, each mirror element may be coupled to a first pair of electrodes to cause clockwise and counter-clockwise rotation about a first axis and a second pair of electrodes to cause clockwise and counter-clockwise rotation about a second axis orthogonal to the first axis. The structure of a mirror array and the associated electrodes may be substantially more complex than that shown in the simplified schematic detail view **115**. For example, U.S. Pat. No. 6,628,041 describes a MEMS mirror array having two-axis mirror motion and comb actuators.

Referring now to FIG. 2, an environment **295** for the application of an optical circuit switch **200** may include a network **290** and a network controller **210**. The optical circuit switch **200** may be the optical circuit switch **100** or may be a compound optical circuit switch including multiple copies of the optical circuit switch **100**. When the optical circuit switch **200** is a compound optical circuit switch, the multiple copies of the optical circuit switch **100** may be collocated or distributed. The optical circuit switch **200** may be disposed within the network **290** and may function to switch optical connections between other nodes (not shown) within the network **290**. The network **290** may be, for example, a wide area network, a local area network, a storage area network, a private network within a data center or computer cluster, and may be or include the Internet. While the connections switched by the optical circuit switch **200** are optical, other connections within the network **290** may be wired and/or wireless.

The network controller **210** may be a computing device that provides a graphic user interface or a command line interface for a network operator to enter connection commands (i.e. commands to make or break one or more optical connections) for the optical circuit switch **200**. The network controller **210** may be a computing device running network management software, in which case connection commands for the optical circuit switch **200** may be generated automatically by the network controller **210**.

A communications link **215** between the optical circuit switch **200** and the network controller **210** may be in-band, which is to say the communications link **215** may be a path within the network **290**. In this case, the optical circuit switch may have a wired, wireless, or optical connection to the network in addition to the optical connections being switched. The communications link **215** may be out-of-band, which is to say the communications link **215** may be a dedicated connection or a connection via a command network independent from the network **290**. A configuration in which the network controller **210** executes network management

5

software to automatically provide connection commands to the optical circuit switch **200** via an out-of-band communications link **215** is an example of what is commonly called a “software defined network”.

FIG. **3** is a high-level block diagram of the control and mirror driver portions of an optical circuit switch **300**, which may be the optical circuit switch **100**. The optical circuit switch **300** may include a switch controller **390**, an input optical monitoring module **370**, an output optical monitoring module **380**, and a plurality of mirror driver circuits **350**. The optical circuit switch **300** may include one mirror driver circuit **350** for each mirror in two mirror arrays if the individual mirror elements are rotatable about a single axis. The optical circuit switch **300** may include two mirror driver circuits **350** for each mirror in the mirror arrays if the individual mirror elements are rotatable about two orthogonal axes. Each mirror driver circuit **350** may have, for example, two selectable outputs to drive one or the other of a pair of electrodes, as described in pending patent application Ser. No. 13/787,621.

The switch controller **390** may include a command interpreter **320** and a position optimizer **330** which jointly maintain a connection state table **340**. The switch controller **390** may receive connection commands from an external source such as the network controller **210**. The switch controller **390** may receive connection commands from some other source or in some other manner.

The command interpreter **320** may be responsive to a set of connection commands received by the switch controller **390**. The set of connection commands may include, for example “Break a-b” and “Make a-b”. These commands may respectively instruct the optical circuit switch **300** to either break an existing connection between ports a and b (where a is an integer input number and b is an integer output number), or to make a new connection between ports a and b. The set of connection commands may include a mass connection command, which may list multiple connections to be made. The mass connection command may be used, for example, when the optical circuit switch is initially integrated into a network or when substantial reconfiguration of the network or data center is required.

The command interpreter **320** may include or have access to a port map **322**. As previously described, to allow the use of mirror arrays with a small number of nonoperational mirror elements, the number of mirror elements in each mirror array may be larger than the number of inputs or outputs. Each input and output may be coupled to a known operational mirror element in the respective mirror array. The port map **322** may be a table containing data relating each input to a mirror element in a first mirror array, and data relating each output to a mirror element in a second mirror array. The data in the port map **322** may be specific to the particular first and second mirror arrays used in the optical circuit switch **300**.

There may be some performance variation from mirror element to mirror element and/or from mirror array to mirror array. In particular, there may be some variation in the mirror element rotation angle versus applied voltage characteristics within and between mirror arrays. The command interpreter **320** may include or have access to a mirror calibration table **324** which contains data describing the performance of each mirror element. For example, the mirror calibration table **324** may store the rotation angle versus voltage characteristic of each mirror element. The mirror calibration table **324** may store, for all possible pairs of input and output elements, a set of voltages that, when applied to the appropriate electrodes, will cause the mirror elements to rotate to make the desired connection. The data in the mirror calibration table **324** may be specific to the particular mirror arrays used

6

in the optical circuit switch **300**. The data in the mirror calibration table **324** may be derived, for example, from the results of tests performed on the particular mirror arrays used in the optical circuit switch **300**.

The data stored in the mirror calibration table **324** may indicate nominal voltages required to initially make desired connections through the optical circuit switch **300**. However, once voltages are applied to electrodes associated with a pair of input and output mirror elements to initially make a connection, the positions of the mirror elements may drift over time. The result of mirror element drift may be failure or degradation (e.g. increased insertion loss) of the connection. The mirror arrays used in the optical circuit switch **300** may be fabricated by chemical micromachining of a silicon substrate. For example, each mirror element may consist of a reflective coating on a silicon slab that is connected to the silicon substrate by narrow silicon elements that function as torsion bars. Each silicon mirror slab may be free to rotate about the axis or axes defined by the torsion bars. Mirror element drift may be due to mechanical stress relief of the torsion bars over time. Further, all or portions of the silicon surfaces of the mirror array may be coated with SiO₂ or some other dielectric. Electric charge trapped at defects in the insulators layers may contribute to mirror element drift over time. Other causes may also contribute to mirror element drift.

The position optimizer **330** may receive data from the input optical monitoring module **370** and the output optical monitoring module **380** indicating the power levels at the inputs and the outputs, respectively. The position optimizer **330** may determine the insertion loss of each active optical connection (i.e. each optical connection where light is present) from the respective input and output power levels. The position optimizer **330** may periodically adjust the positions of some or all of the mirror elements to minimize the insertion loss of each optical connection. For example, to optimize a connection, the position optimizer **330** may make incremental changes in the position of one of the mirror elements used in the connection and observe the resulting effect on insertion loss. The optimum position of the mirror element may then be found using a hill climbing algorithm or a similar algorithm. The position of each mirror element may be optimized periodically. The time interval between successive optimizations of each mirror element may be short (on the order of seconds) compared to the time constant of the mirror element drift (on the order of hours). Periodic optimization of the position of each mirror element may automatically compensate for mirror element drift.

The command interpreter **320** and the position optimizer **330** may jointly maintain and share the connection state table **340**. The connection state table **340** may include data indicative of the state or status of each port of the optical circuit switch **300**. Data included in the connection state table **340** for each port may include a first flag indicating if the respective port is available or committed to a connection, and a second flag indicating if the connection has actually been made. The connection state table **340** may include, for inputs, a third flag indicating if light is present at the respective input. For each port that is committed to a connection, the connection state table **340** may also include the identity of the port at the other end of the connection, the mirror element associated with the port, the voltages presently applied to the electrodes associated with the mirror element, and temporal data such as when the connection was first made and when the position of the mirror element was most recently optimized.

Referring now to FIG. **4**, an exemplary compound optical circuit switch **400** may be capable of making a unidirectional connection between any of 640 input ports and any of 640

7

output ports. The 640 input ports and 640 output ports may be grouped in pairs to provide 640 full-duplex ports, as shown in FIG. 4. In this context, a full-duplex port is an input paired with an output to accommodate bidirectional communications. The compound optical circuit switch **400** may be capable of making a bidirectional connection between any one of 640 full-duplex ports to any other of the 640 full duplex ports. In this context, a full-duplex port is an input paired with an output to accommodate bidirectional communications. The compound optical circuit switch **400** may be fully non-blocking, which is to say a bidirectional connection between any two selected full-duplex ports can be made regardless of any possible combination of existing connections between other full-duplex ports.

The compound optical circuit switch **400** may include six optical circuit switches **410-1** to **410-4** and **420-1** to **420-2**, each of which may be the optical circuit switch **100**. Each of the optical circuit switches **410-1** to **410-4** and **420-1** to **420-2** may be configured to connect a group of 320 inputs to a group of 320 outputs. More specifically, each of the optical circuit switches **410-1** to **410-4** and **420-1** to **420-2** may selectively make up to 320 connections, where each connection conveys an optical signal from an input to an output. The choice of 320 input and outputs per optical circuit switch is exemplary, and the optical circuit switches **410-1** to **410-4** and **420-1** to **420-2** may have more or fewer inputs and outputs.

The six 320×320 optical circuit switches may be arranged as four 1st-tier switches **410-1**, **410-2**, **410-3**, and **410-4** and two 2nd-tier switches **420-1**, **420-2**. The 640 full-duplex ports of the compound optical circuit switch **400** may be connected to respective input/output pairs of the 1st-tier optical circuit switches **410-1** to **410-4**. Specifically 160 inputs and 160 outputs of each 1st-tier optical circuit switch may be connected respectively to 160 full-duplex ports. For example, the 160 inputs and 160 outputs of optical circuit switch **410-1** may be connected to full-duplex ports numbered from 1 to 160. Similarly, optical circuit switch **410-2** may be connected to full-duplex ports **161** to **320**, optical circuit switch **410-3** may be connected to full-duplex ports **321** to **480**, and optical circuit switch **410-4** may be connected to full-duplex ports **481** to **640**. The full-duplex ports may be numbered in some other manner.

The other inputs and outputs of the 1st-tier optical circuit switches **410-1** to **410-4** may be connected to the 2nd-tier optical circuit switches **420-1** and **420-2**. Specifically 80 outputs of each of the four 1st-tier optical circuit switches **410-1** to **410-4** may be connected to respective inputs of each of the 2nd-tier optical circuit switches **420-1**, **420-2**. 80 inputs of each of the four 1st-tier optical circuit switches **410-1** to **410-4** may be connected to respective outputs of each of the 2nd-tier optical circuit switches **420-1**, **420-2**.

Referring now to FIG. 5, connections between full-duplex ports provided on the same 1st-tier optical circuit switch may be made within the 1st-tier optical circuit switch. For example, a connection between two of the full duplex ports **161** to **320** can be made within the 1st-tier optical circuit switch **410-2**, as illustrated by the arrow **502**. Such connections will be referred to herein as “simple connections”. A special case of a simple connection is when the input and output of a full duplex port are connected to each other to provide an optical loop-back. A loop-back connection may be useful during diagnostic testing of a network.

Connections between full-duplex ports provided by different 1st-tier optical circuit switches **410-1** to **410-4** may be made via one of the second tier optical circuit switches **420-1** and **420-2**, as illustrated by the optical path **504**. Such connections will be referred to herein as “compound connec-

8

tions”, where “compound” has its normal meaning of “composed of the union of several elements”. Each compound connection includes connections through two different 1st-tier optical circuit switches and a connection through a 2nd-tier optical circuit switch. These connections will be referred to, in the direction of optical signal flow, an “input 1st tier connection” **506**, a “2nd-tier connection” **508**, and an “output 1st-tier connection” **510**. The switches involved in a compound connection will be referred to, in the direction of optical signal flow, the input 1st-tier switch, the 2nd-tier switch, and the output 1st-tier switch.

Referring back to FIG. 4, the compound optical circuit switch **400** may include a compound connection controller **430** having primary responsibility for routing compound connections through compound optical circuit switch. The compound connection controller **430** may receive global connection commands from a network controller such as the network controller **210**. In this context, a “global connection command” is a command directed to the compound optical circuit switch **400** as a whole, as opposed to a “local connection command” directed to one nxn optical circuit switch **410-1** to **410-4**, **420-1**, **420-2** within the compound optical circuit switch **400**. Each global connection command may require one or more connections through the compound optical circuit switch **400** to be made and/or broken. When a received global connection command calls for a simple connection to be made or broken, the compound connection controller **430** may relay the global connection command as a local connection command to the appropriate 1st-tier optical circuit switch **410-1** to **410-4**. When a received global connection command calls for a compound connection to be made or broken, the compound connection controller **430** may select a path through the compound optical circuit switch **400** and send individual local connection commands to the appropriate 1st-tier optical circuit switches **410-1** to **410-4** and the selected and 2nd-tier optical circuit switch **420-1** or **420-2**.

Referring now to FIG. 6, a generalized compound optical circuit switch **600** may be capable of making a unidirectional connection between any of kn input ports and any of kn output ports, where n is a number of inputs and outputs provided by an nxn optical circuit switch and k is an integer greater than one. The kn input ports and kn output ports may be grouped in pairs to provide kn full-duplex ports. The compound optical circuit switch **600** may be capable of making a bidirectional connection between any one of the kn full-duplex ports to any other of the kn full duplex ports. The compound optical circuit switch **600** may be fully non-blocking, which is to say a bidirectional connection between any two selected full-duplex ports can be made regardless of any possible combination of existing connections between other full-duplex ports.

The compound optical circuit switch **600** may include 2k nxn 1st-tier optical circuit switches. Each of the 2k nxn 1st-tier switches may be configured to connect a group of n inputs to a group of n outputs. Each of the 2k nxn 1st-tier switches may selectively make up to n connections, where each connection conveys an optical signal from an input to an output. The kn full-duplex ports of the compound optical circuit switch **600** may be connected to respective input/output pairs of the 1st-tier optical circuit switches **610-1** to **610-2k**. Specifically n/2 inputs and n/2 outputs of each 1st-tier optical circuit switch may be paired to provide n/2 full-duplex ports.

The compound optical circuit switch **600** may include j m×m 2nd-tier optical circuit switches **620-1** to **620-j**. Each of the j m×m 2nd-tier switches may be configured to connect a group of m inputs to a group of m outputs. Each of the j m×m

2^{nd} -tier switches may selectively make up to m connections, where each connection conveys an optical signal from an input to an output.

The other inputs and outputs of the 1^{st} -tier optical circuit switches **610-1** to **610-2k** may be connected to the 2^{nd} -tier optical circuit switches **620-1** and **620-j**. Specifically $n/2j$ outputs of each of the $2k$ 1^{st} -tier optical circuit switches **610-1** to **610-2k** may be connected to respective inputs of each of the 2^{nd} -tier optical circuit switches **620-1**, **620-j**. $n/2j$ inputs of each of the $2k$ 1^{st} -tier optical circuit switches **610-1** to **610-2k** may be connected to respective outputs of each of the 2^{nd} -tier optical circuit switches **620-1**, **620-j**. In order for each input or output of a 1^{st} -tier switch to be connected to a respective output or input of a 2^{nd} -tier switch, the relationship $kn=jm$ may be satisfied. The compound optical circuit switch **400** of FIG. **4** is an instantiation of the compound optical circuit switch **600** with $n=m=320$ and $k=j=2$. In other embodiments of the compound optical circuit switch **600**, j , k , m , and n may have other values.

The compound optical circuit switch **600** may include a compound connection controller **630** having primary responsibility for routing compound connections through compound optical circuit switch. The compound connection controller **630** may receive global connection commands from a network controller such as the network controller **210**. Each global connection command may require one or more connections through the compound optical circuit switch **600** to be made and/or broken. When a received global connection command calls for a simple connection to be made or broken, the compound connection controller **630** may simply relay the global connection command as a local connection command to the appropriate 1^{st} tier optical circuit switch **610-1** to **610-2k**. When a received global connection command calls for a compound connection to be made or broken, the compound connection controller **630** may select a path through the compound optical circuit switch **600** and send individual local connection commands to the appropriate 1^{st} -tier optical circuit switches **610-1** to **610-2k** and the selected 2^{nd} -tier optical circuit switch **620-1** to **620-j**.

Briefly reviewing the description of FIG. **1**, an optical circuit switch **100** may include tap couplers (of which only tap coupler **114-1** is identified) to direct a sample portion of each input signal to an input optical monitoring module **170** that measures an optical power level of each input. The optical circuit switch **100** may also include tap couplers (of which only tap coupler **154-1** is identified) to direct a sample portion of each output signal to an output optical monitoring module **180** that measures an optical power level of each output. A controller **190** may control the position of mirrors within mirror arrays **130**, **140** to optimize each connection through the optical circuit switch **100** based on the respective input and output power measurements.

However, in a compound optical circuit switch such as the compound optical circuit switch **600**, every input to a 2^{nd} -tier switch **620-1** to **620-j** comes from an output of one of the 1^{st} -tier switches **610-1** to **610-2k**. Thus, ignoring possible losses in the fiber optic connections between the 1^{st} -tier and 2^{nd} -tier switches, the input power levels at the inputs of the 2^{nd} -tier switches will be the same as the output power levels at the outputs of the 1^{st} -tier switches. Thus it is not necessary for a compound optical circuit switch to include both output power monitoring in the 1^{st} -tier switches and input power monitoring in the 2^{nd} -tier switches. Similarly, every output from a 2^{nd} -tier switch **620-1** to **620-j** goes to an input of one of the 1^{st} -tier switches **610-1** to **610-2k**. Thus it is not necessary for a compound optical circuit switch to include both output power monitoring in the 2^{nd} -tier switches and input

power monitoring in the 1^{st} -tier switches. Power monitoring in the 1^{st} -tier switches alone will perform the functions for both the 2^{nd} -tier and 1^{st} -tier switches because all connections, both simple and compound, must pass through at least one of the 1^{st} -tier switches.

Referring now to FIG. **7**, another compound optical circuit switch **700** may be capable of making a bidirectional connection between any one of kn full-duplex ports to any other of the kn full duplex ports, where n is a number of inputs and outputs provided by an $n \times n$ optical circuit switch and k is an integer greater than zero. The compound optical circuit switch **700** may include $2k$ first-tier switches **710-1** to **710-2k** and j second-tier switches **720-1** to **720-j**. The 1^{st} -tier and 2^{nd} -tier switches may be interconnected as described with respect to FIG. **6**. The compound optical circuit switch **700** may include a compound connection controller **730** having primary responsibility for routing compound connections through compound optical circuit switch as previously described.

Each 1^{st} -tier switch **710-1** to **710-2k** may include tap couplers on each input and output and respective input optical monitoring modules **770-1** to **770-2k** and output optical monitoring modules **780-1** to **780-2k**. Each 2^{nd} -tier switch **720-1** to **720-j** may not include taps couplers or optical monitoring modules. Instead, the respective switch controllers **725-1** to **725-j** of the 2^{nd} -tier switches may receive power measurement data **718-1** to **718-2k** from the respective switch controllers **715-1** to **715-2k** of the 1^{st} tier switches. Power measurement data **718-1** to **718-2k** may be communicated from the 1^{st} -tier switches to the 2^{nd} -tier switches via multiple dedicated connections (as shown) or via one or more shared bus or network. For example, the 1^{st} -tier switches **710-1** to **710-2k** may transmit power measurement data in rotation over a shared bus or network. Each 1^{st} -tier switch may transmit power measurement data for all inputs and outputs, or only those inputs and outputs connected to one of the 2^{nd} -tier switches **720-1** to **720-j**. Each 2^{nd} -tier switch (or the switch controllers **725-1** to **725-j** or the compound connection controller **730**) may have knowledge of the interconnections between the 1^{st} -tier switches and each 2^{nd} -tier switch but power measurement data may only be captured for only the 1^{st} -tier inputs and outputs to which it is actually connected.

Referring now to FIG. **8**, another compound optical circuit switch **800** may be capable of making a bidirectional connection between any one of kn full-duplex ports to any other of the kn full duplex ports, where n is a number of inputs and outputs provided by an $n \times n$ optical circuit switch and k is an integer greater than zero. The compound optical circuit switch **800** may include $2k$ first-tier switches **810-1** to **810-2k** and j second-tier switches **820-1** to **820-k**. The 1^{st} -tier and 2^{nd} -tier switches may be interconnected as described with respect to FIG. **6**. The compound optical circuit switch **800** may include a compound connection controller **830** having primary responsibility for routing compound connections through compound optical circuit switch as previously described.

Each 1^{st} -tier switch **810-1** to **810-2k** may include tap couplers on each input and output and respective input optical monitoring modules **870-1** to **870-2k** and output optical monitoring modules **880-1** to **880-2k**. Each 2^{nd} -tier switch **820-1** to **820-j** may not include taps couplers or optical monitoring modules. Instead, the respective switch controllers **815-1** to **815-2k** of the 1^{st} -tier switches may provide power measurement data **818-1** to **818-2k** to a master controller **840**. The master controller **840** may be a separate computing device, or may be integrated with the compound connection controller **830** or one of the switch controllers **815-1** to **815-**

11

2k or **825-1** to **825-j**. Power measurement data **718-1** to **718-2k** may be communicated from the 1st-tier switches to the master controller **840** via multiple dedicated connections (as shown) or via one or more shared bus or network. The master controller may be knowledgeable of the interconnections between the 1st-tier and 2nd-tier switches. The master controller **840** may distribute the appropriate power measurement data **835-1** to **835-j** to each 2nd-tier switch **820-1** to **820-j**. The master controller **840** may also coordinate optimization of compound connections between the 1st-tier and 2nd-tier switches.

Referring now to FIG. 9, another compound optical circuit switch **900** may be capable of making a bidirectional connection between any one of 512 full-duplex ports to any other of the 512 full duplex ports. The compound optical circuit switch **900**, like the compound optical circuit switch **400** of FIG. 4, may include four first-tier switches **910-1** to **910-4**, each of which can make half-duplex connections between 320 input and output ports. Unlike the compound optical circuit switch **400**, 128 input and output ports of each 1st-tier switch **910-1** to **910-4** are used to provide a total of 512 full duplex ports of the compound optical circuit switch. 192 input and output ports of each 1st-tier switch **910-1** to **910-4** are connected to three second-tier switches **920-1** to **920-3**. The addition of a third 2nd-tier switch provides redundancy such that all possible full-duplex connections through the compound optical circuit switch **900** can be made even in the event of a complete failure of one of the 2nd tier switches **920-1** to **920-3**. Redundancy is provided at the expense of a reduction in the number of full duplex ports (**512** as opposed to **640** for the compound optical circuit switch **400**) and the addition of the third 2nd-tier switch. Redundancy may be provided in higher port count compound optical circuits switches by incorporating at least one redundant 2nd-tier switch connected to input and output ports of each 1st-tier switch.

Description of Processes

FIG. 10 is a flow chart of a process **1000** for optimizing a connection through a compound optical circuit switch such as the compound optical circuit switches **400**, **600**, **700**, and **800**. The process **1000** may start at **1011** and end at **1090** after a single unidirectional connection has been optimized. Although the process **1000** is not inherently cyclic, the process **1000** may be repeated periodically, as indicated by the dashed arrow **1095**, to re-optimize the connection to correct for factors such as mirror element drift and/or temperature changes.

Multiple instantiations of the process **1000** may proceed sequentially and/or concurrently to optimize a large number of connections through the compound optical circuit switch. Note that two instantiations of the process **1000** are required to optimize both directions of a full-duplex simple connection. For example, the compound optical circuit switch **400** of FIG. 4 can provide full-duplex connections between 640 full-duplex ports, which is equivalent to 640 unidirectional connections between individual inputs and outputs. The compound optical circuit switch **400** may run up to 640 instantiations of the process **1000** to optimize all connections. The compound optical circuit switches **600**, **700**, and **800** may run up to kn instantiations of the process **1000**.

At **1020** a determination may be made whether or not the connection to be optimized is a simple connection (see, e.g., simple connection **520** in FIG. 5). When the connection to be optimized is a simple connection ("yes" at **1020**), the connection is made through a single 1st-tier switch. In this case, the

12

mirror positions in the 1st-tier switch may be optimized at **1030** using a local search optimization technique. For example, a hill climbing algorithm may be used to optimize the mirror position. A mirror position may be incrementally changed and a determination may be made if the position change improved or degraded the insertion loss of the connection through the switch. Successive incremental changes may be made until an optimum mirror position is determined. Sequential hill-climbing algorithms may be performed for each of two rotation axes and two mirror elements for each connection. After the positions of both mirror elements on both axes have been optimized, the process **1000** may end at **1090**.

When a determination is made at **1020** that the connection is not a simple connection ("no" at **1020**), the connection must be, by default, a compound connection through two 1st-tier switches and a 2nd-tier switch. In this case, the mirror positions within the three switches may be optimized sequentially at **1040**, **1050**, and **1060** using hill climbing or other optimization algorithms as previously described. Sequential optimization is necessary to avoid the ambiguity that would inherently occur if hill climbing algorithms were run simultaneously on multiple mirror elements along the same connection. The order in which the mirror positions in the three switches are optimized is unimportant, so long as the mirror positions in only one switch are being optimized at any given time. After the mirror positions within the three switches have been optimized, the process **1000** may end at **1090**.

The process **1000** may be supervised by a master controller such as the master controller **840** in the compound optical circuit switch **800**. The master controller may control the sequence **1040**, **1050**, **1060** in which 1st-tier and 2nd-tier switch optimize connections. For example, for each compound connection, the master controller may authorize a first switch to optimize mirror positions at **1040**. After receiving confirmation from the first switch that its optimization has been completed, the master controller may authorize the second switch to optimize mirror positions at **1050** and, subsequently, the third switch to optimize mirror positions at **1060**. The master controller may also determine how often the process **1000** should be repeated (dashed arrow **1095**).

FIG. 11 is a flow chart of another process **1100** for optimizing a connection through a compound optical circuit switch that does not include a master controller, such as the compound optical circuit switches **400**, **600**, and **700**. The process **1100** may start at **1105** when a first connection is made through the compound optical circuit switch and may continue perpetually so long as the compound optical circuit switch is in service. The process **1100** is inherently cyclic, and will repeat periodically to re-optimize the connection to correct for factors such as mirror element drift and/or temperature changes.

Multiple instantiations of the process **1100** may proceed sequentially and/or concurrently to optimize a large number of connections through the compound optical circuit switch. Note that two instantiations of the process **1100** are required to optimize both directions of a full-duplex simple connection. For example, the compound optical circuit switch **400** of FIG. 4 can provide full-duplex connections between 640 full-duplex ports, which is equivalent to 640 unidirectional connections between individual inputs and outputs. The compound optical circuit switch **400** may run up to 640 instantiations of the process **1100** to optimize all connections. The compound optical circuit switches **600** and **700** may run up to kn instantiations of the process **1100**.

13

As shown in FIG. 11, the process 1100 is controlled by the input 1st-tier switch for each connection. An alternate version of the process 1100 may be controlled by the output 1st-tier switch of each connection.

At 1110, the input 1st-tier switch may determine whether or not it is time to start a next optimization cycle. This determination may be based, for example, by a hardware or software timer that initiates an optimization cycle at periodic intervals. If the determination is made that it is not yet time to begin a new cycle ("no" at 1110) the process 1100 may idle at 1110.

When a determination is made at 1110 to initiate a new optimization cycle, the positions of mirrors within the input 1st-tier switch may be optimized at 1120 using a local search optimization technique. For example, a hill climbing algorithm may be used to optimize the mirror position. A mirror position may be incrementally changed and a determination may be made if the position change improved or degraded the insertion loss of the connection through the switch. Successive incremental changes may be made until an optimum mirror position is determined. Sequential hill-climbing algorithms may be performed for each of two rotation axes and two mirror elements for each connection.

After the positions of both mirror elements on both axes have been optimized at 1120, a determination may be made at 1130 whether or not the connection is a simple connection. When the connection is a simple connection ("yes" at 1130), the connection is completed within the input 1st-tier switch (which is inherently also the output 1st-tier switch). Thus the optimization performed at 1120 optimizes the entire simple connection. In this case, the process 1100 may return to 1110 to await the start of the next cycle.

When a determination is made at 1130 that the connection is not a simple connection ("no" at 1130), the connection must be, by default, a compound connection through two 1st-tier switches and a 2nd-tier switch. In this case, at 1140, the input 1st-tier switch may pass a token to the appropriate 2nd-tier switch. The token may be passed, for example, using the same bus, network, or other communications path used to pass power measurements from the 1st-tier switches to the 2nd-tier switches.

Upon receipt of the token, the 2nd-tier switch may optimize the positions of the appropriate mirrors at 1150. When complete, the 2nd-tier switch may pass the token to the appropriate output 1st tier switch at 1160. Upon receipt of the token, the output 1st-tier switch may optimize the positions of the appropriate mirrors at 1170 to complete the optimization of the entire compound connection. The process 1105 may then return to 1110 to await the next optimization cycle.

FIG. 12 is a flow chart of a process 1200 for making a full-duplex connection through a compound optical circuit switch, such as the compound optical circuit switches 400, 600, 700, and 800. The process 1200 may start at 1205 when a command to make a connection between to designated ports is received by the compound optical circuit switch. The command may be received, for example, from a network controller such as the network controller 210. The process 1200 may end at 1295 after a single full-duplex (bidirectional) connection has been made. The process 1200 may be repeated each time a new connection is made through the compound optical circuit switch.

At 1210, a determination may be made whether or not the two ports to be connected are available, which is to say the two ports to be connected are not already used in a prior connection. If one or both of the two ports is used in an existing connection and thus not available ("no" at 1210), an error message may be issued to the network controller at 1220 and the process 1200 may end at 1295. If a determination is

14

made that the two ports are available ("yes" at 1210), the process 1200 may proceed to 1220. The actions at 1210 and 1215 are optional and in some compound optical circuit switches, the process 1200 may proceed immediate to 1220 from the start at 1205.

At 1220, a determination may be made whether or not the connection to be optimized is a simple connection. When the connection to be optimized is a simple connection ("yes" at 1220), the connection can be made through a single 1st-tier switch. In this case, the connection may be made through the appropriate 1st-tier switch at 1225 and the process 1200 may end at 1295.

When a determination is made at 1220 that the connection is not a simple connection ("no" at 1220), the connection must be, by default, a compound connection through two 1st-tier switches and a 2nd-tier switch. In this case, connection paths for each direction of the full-duplex connection may be selected from among the available paths at 1230. For example, when the first connection made through the compound optical circuit switch 400 is a compound connection, 80 different paths will be available from the input 1st-tier switch to either of the 2nd-tier switches, and 80 different paths will be available from the selected 2nd-tier switch to the output 1st-tier switch, for a total of 2×80×80=12,800 different possible routings for the connection. At the other extreme, after 639 connections have been made, only a single connection path will be available for the 640th connection. The paths between the 1st-tier and 2nd-tier switches may be selected at 1250 sequentially, randomly, or in some other manner. The bidirectional paths of a full-duplex connection may commonly, but not necessarily be routed through the same 2nd-tier switch.

Particular connection paths for each direction of the full-duplex connection may be selected from among the available paths at 1230 randomly, or in a predetermined order, or based on one or more selection criteria. For example, a preferred 2nd-tier switch may be specified in the command received at 1205. The various 1st-tier and 2nd-tier switches making up a compound optical circuit switch are not necessarily co-located. The 1st-tier and 2nd-tier switches of a compound optical circuit switch may be physically distributed between multiple equipment racks, multiple buildings, and even multiple cities. When the 1st-tier and 2nd-tier switches of a compound optical circuit switch are physically distributed, a selection criteria applied at 1230 may be to minimize the physical distance of the paths. Minimizing the physical distance of the paths may, for example, lower the probability of the connection being lost due to a cable failure. Different physical and logical security levels may be imposed on different 1st-tier and 2nd-tier switches making up a compound optical circuit switch. In this case, a selection criteria applied at 1230 may be to ensure a particular security level as defined in the command received at 1205. Other criteria may be used at 1230 to select particular paths from a plurality of available paths. When multiple selection criteria are applied to a full duplex connection, priorities or weights may be assigned to the selection criteria.

After the connections paths have been selected at 1230, the input 1st tier switch may be instructed to make the input 1st-tier connections at 1260. Making a connection in an optical circuit switch may require an extended period of time (for example tens or hundreds of milliseconds) since the mirror elements may be moved gradually to avoid mechanical overshoot, ringing, and possible damage. Making the input 1st-tier connections at 1260 allows the input 1st-tier connections be optimized at 1265 (assuming light is present at the inputs to the connections) without having to wait for the movement of the mirrors in the 2nd-tier switch and the output 1st-tier switch.

15

The 2nd-tier connections may be made at **1270**, concurrent with the optimization of the input 1st-tier connection at **1265**. The 2nd-tier connections may be optimized at **1275** after the optimization of the input 1st-tier connections at **1265** is complete. The output 1st-tier connections may be made last at **1280**, which may be concurrent with the optimization of the input 1st-tier connection at **1265** or optimization of the 2nd-tier connection at **1275**. The output 1st-tier connections may be optimized at **1285** after the optimization of the 2nd-tier connections at **1275** is complete. The process **1200** may then end at **1295**.

Portions of the process **1200** may be performed and/or supervised by a compound connection controller such as the compound connection controllers **430**, **630**, **730** and **830**. The compound connection controller may receive connection commands at **1205**, determine if the ports are available at **1200** and issue error messages at **1205**. When a simple connection is made, the compound connection controller may relay the connection command to the appropriate 1st-tier switch to make the connection at **1225**. When a compound connection is made, the compound connection controller may select the connection path at **1230** and provide local commands to the appropriate 1st-tier and 2nd-tier switches to make the connection at **1260-1285**.

Optical signals routed through optical circuit switch will suffer insertion loss due to small, but cumulative, losses at the movable mirrors, collimating and focusing lenses, optical fibers, tap couplers, and other components of the optical circuit switch. Further, minor variations in these components may result in variations in the expected insertion loss (i.e. the insertion loss after mirror positions are optimized) of different connections through an optical circuit switch. The variations in insertion loss can be exaggerated in a compound optical circuit switch since each compound connection consists of three optical circuit switch connections in series. Excessive cumulative insertion loss over an optical communications path may result in low signal-to-noise ratio of the received optical signal which may, in turn, cause increased bit error rate. Network controllers, such as the network controller **210**, may strive to limit the cumulative insertion loss in each optical communications path. To this end, a network controller may establish a loss budget for each communication path, which may include an insertion loss target for some or all connections through optical circuit switched.

FIG. **13** is a flow chart of another process **1300** for making a full-duplex connection through a compound optical circuit switch, such as the compound optical circuit switches **400**, **600**, **700**, and **800**. The process **1300** is similar to the process **1200**, except that the process **1300** considers expected insertion loss when making connections and, in particular, when selecting paths for compound connections. To this end, an expected loss for every possible connection through each of the 1st-tier and 2nd-tier switches may be stored in an expected loss table **1335**. The data in the expected loss table may be derived, for example, from manufacturer's test data on each of the optical circuit switches.

The process **1300** may start at **1305** when a command to make a connection is received by the compound optical circuit switch. The actions **1310** to **1325** and **1360** to **1385** in the process **1300** are essentially identical to the counterpart actions in the process **1200**. Complete descriptions of similar actions will not be repeated. The process **1300** may end at **1395** after a single full-duplex (bidirectional) connection has been made.

The command received at **1315** may be provided, for example, by a network controller such as the network controller **210**. The command may identify a pair of full-duplex

16

ports to be connected. The command may optionally include data indicating a respective insertion loss target for the connection to be made. For example, the command received at **1305** may specify a maximum acceptable insertion loss for the connection. The command received at **1305** may include a flag or other data indicating the connection should be made with the minimum possible insertion loss. The command may include a flag or other data indicating that the connection can tolerate relatively high insertion loss. The command received at **1305** may include data specifying an insertion loss target in some other manner.

When a determination is made at **1320** that a simple connection will be made, there will be only a single possible optical path for the connection within the appropriate one of the 1st-tier switches. If the command received at **1305** included a loss target for this connection, an expected loss of the connection may be retrieved from the expected loss table **1335**. The expected loss and the loss target may be compared and a determination may be made at **1340** whether or not the expected loss satisfies the loss target. When the loss target is satisfied ("yes" at **1340**) the connection may be made at **1325** and the process **1300** may end at **1395**.

When a determination is made at **1340** that the loss target will not be satisfied ("no" at **1340**), a message to that effect may be issued at **1315**, and the process **1300** may end at **1395**. Alternatively, the connection may be made anyway (for example when no alternative connection paths are available) at **1325**, as indicated by the dashed line **1345**.

When a determination is made at **1320** that a compound connection is required ("no" at **1320**), a connection path for the compound connection may be selected at **1330**. In most circumstances, multiple (possibly hundreds) of alternative connection paths may be available to make a particular compound connection. Each connection path consists of an input 1st-tier connection, a 2nd-tier connection, and an output 1st-tier connection. When multiple connection paths are available, the selection of a particular connection path at **1330** may be based on selection criteria as previously described. When multiple selection criteria are applied to a full duplex connection, priorities or weights may be assigned to the selection criteria.

One selection criteria that may be applied at **1330** is a loss target for the connection. For example, if the loss target is to make the connection with the minimum possible insertion loss, the expected loss table **1335** may be searched for the available path having the lowest insertion loss. If the loss target is expressed as a maximum allowed loss level, the expected loss table **1335** may be searched for the first available with an insertions loss lower than the target level. If the loss target indicates that the connection can tolerate high loss, the expected loss table **1335** may be searched for the available path having the highest insertion loss (to preserve lower insertion loss connections). The connection path may be selected at **1330** in some other manner.

At expected loss of the selected connection path and the loss target may be compared and a determination may be made at **1350** whether or not the expected loss satisfies the loss target. When the loss target is satisfied ("yes" at **1350**) the connection may be made at **1360-1385** as previously described. The process **1300** may then end at **1395**.

When a determination is made at **1350** that the loss target will not be satisfied ("no" at **1350**), a message to that effect may be issued at **1315**, and the process **1300** may end at **1395**. Alternatively, the connection may be made anyway (for example, when no alternative connection path is available) at **1360-1385**, as indicated by the dashed line **1355**.

In the absence of a loss target for a compound connection, or as an alternative to the use of loss targets altogether, the connections paths for compound connections may be selected at **1330** to attempt to equalize the insertion loss of all compound connections. To this end, the insertion loss of each compound connection may be set, to the extent possible, equal to the average expected insertion loss of a compound connection. At **1330**, the connection path may be selected in accordance with the formula

$$IL1_{in} + IL2 + IL1_{out} \approx 2IL1_{av} + IL2_{av} \quad (1)$$

where $IL1_{in}$, $IL2$, and $IL1_{out}$ are the insertion losses (from the expected loss table **1335**) of the selected connections through the input 1^{st} -tier switch, the selected 2^{nd} -tier switch, and the output 1^{st} -tier switch respectively; $IL1_{av}$ and $IL2_{av}$ are the average insertion losses of connections through 1^{st} -tier and 2^{nd} -tier switches, respectively; and the symbol \approx has its normal meaning of “almost equal to”.

Portions of the process **1300** may be performed and/or supervised by a compound connection controller such as the compound connection controllers **430**, **630**, **730** and **830**. The compound connection controller may include the expected loss table **1335**. The compound connection controller may receive connection commands at **1315**, determine if the ports are available at **1310** and issue error messages at **1315**. When a simple connection is made, the compound connection controller may determine if the connection will meet a lost target at **1340** and relay the connection command to the appropriate 1^{st} -tier switch to make the connection at **1325**. When a compound connection is made, the compound connection controller may select the connection path at **1330**, determine if a loss target is satisfied at **1350**, and provide local commands to the appropriate 1^{st} -tier and 2^{nd} -tier switches to make the connection at **1360-1385**.

FIG. **14** is a flow chart of a process **1400** for rebuilding full-duplex compound connections through a compound optical circuit switch, such as the compound optical circuit switches **400**, **600**, **700**, **800**, and **900** in the event of a failure of a 2^{nd} -tier switch. The process **1400** may start at **1410** when an alarm or other indication is received indicating failure of a 2^{nd} tier switch within the compound optical circuit switch. The alarm may be generated with the compound optical circuit switch or may be surmised from externally generated information such as the disruption of a plurality of connections made through the failed 2^{nd} -tier switch. The process **1400** may end at **1490** when the connections broken by the failure of the 2^{nd} -tier switch have been rebuilt to the extent possible.

At **1420**, the compound connections broken by the failure of the 2^{nd} -tier switch may be identified and, optionally, prioritized. For example, a compound connection controller (e.g. **430**, **630**, **730**, **830**, **930**) within the compound optical circuit switch may maintain or table or list of the compound connections made through the compound optical circuit switch. This table may be parsed to identify connections made using the failed 2^{nd} -tier switch.

In general, an optical circuit switch is oblivious to the content communicated over connections made through the switch. Thus an optical circuit switch may be unable, of itself, to prioritize connections for rebuilding. However, priority information may be included in commands received by the optical circuit switch and may be stored in the table of connections. Priority information may also be provided, for example by a network controller such as the network controller **210**, at the time the failure of the 2^{nd} -tier switch is recognized. The priority information may be used at **1420** to prioritize an order in which broken connections will be rebuilt.

When priority information is not available, the compound connections to be rebuilt may be placed in random order or any convenient order.

Each broken compound connection may be rebuilt in sequence from **1430** to **1460**. At **1430** a first broken compound connection may be selected in accordance with the order determined at **1420**. At **1440**, a determination may be made whether or not a path is available to rebuild the selected connection. Each broken full duplex compound connection connects an input/output port pair at a first 1^{st} -tier switch with an input/output port pair at a second 1^{st} -tier switch. Since the two directions of the full duplex compound connection did not necessarily pass through the same 2^{nd} tier switch, one or both of the directions of the full duplex compound connection may need to be rebuilt. In order to rebuild a connection, it is necessary that a path is available between the first and second 1^{st} -tier switches via one of the working 2^{nd} tier switches.

In a compound optical circuit switch without redundancy, such as the compound optical circuit switches **400**, **600**, **700**, and **800**, paths to rebuild broken compound connections will be available only to the extent that some ports of other 2^{nd} -tier switches were unused prior to the failure of the failed 2^{nd} -tier switch. If a path is available to rebuild the compound connection identified at **1430**, the connection may be rebuilt at **1450**. Rebuilding the compound connection at **1450** may include issuing local connection commands to the appropriate 1^{st} -tier and 2^{nd} -tier switches to make and optimize the necessary connections, such as described in conjunction with actions **1260-1285** of the process **1200**.

In a compound optical circuit switch with redundancy, such as the compound optical circuit switch **900**, a path to rebuild any broken compound connection is guaranteed. In such a compound optical circuit switch, the determination at **1440** is unnecessary and the connection selected at **1430** may be rebuilt at **1450**.

After one or both directions of a compound connection are rebuilt at **1450**, or when a determination is made at **1440** that no path is available, the process **1400** may proceed to **1460**. At **1460**, a determination may be made if there are more broken compound connections that may possibly be rebuilt. When one or more broken compound connections are identified, the process **1400** may return to **1430** to select the next broken compound connection. The actions from **1430** to **1460** may be repeated until all broken compound connections have been considered. When all broken compound connections have been considered (“No” at **1460**), the process may end at **1490**.

Closing Comments

Throughout this description, the embodiments and examples shown should be considered as exemplars, rather than limitations on the apparatus and procedures disclosed or claimed. Although many of the examples presented herein involve specific combinations of method acts or system elements, it should be understood that those acts and those elements may be combined in other ways to accomplish the same objectives. With regard to flowcharts, additional and fewer steps may be taken, and the steps as shown may be combined or further refined to achieve the methods described herein. Acts, elements and features discussed only in connection with one embodiment are not intended to be excluded from a similar role in other embodiments.

As used herein, “plurality” means two or more. As used herein, a “set” of items may include one or more of such items. As used herein, whether in the written description or the claims, the terms “comprising”, “including”, “carrying”, “having”, “containing”, “involving”, and the like are to be

19

understood to be open-ended, i.e., to mean including but not limited to. Only the transitional phrases “consisting of” and “consisting essentially of”, respectively, are closed or semi-closed transitional phrases with respect to claims. Use of ordinal terms such as “first”, “second”, “third”, etc., in the claims to modify a claim element does not by itself connote any priority, precedence, or order of one claim element over another or the temporal order in which acts of a method are performed, but are used merely as labels to distinguish one claim element having a certain name from another element having a same name (but for use of the ordinal term) to distinguish the claim elements. As used herein, “and/or” means that the listed items are alternatives, but the alternatives also include any combination of the listed items.

It is claimed:

1. A compound optical circuit switch to provide selectable optical connections between a plurality of input ports and a plurality of output ports, comprising:

two or more 1st-tier switches, each of the plurality of input ports connected to a respective input of one of the 1st-tier switches, and each of the plurality of output ports connected to a respective output of one of the 1st-tier switches;

one or more 2nd-tier switches coupled to the 1st-tier switches; and

a compound connection controller configured to:

receive a global connection command identifying an input port from the plurality of input ports and an output port from the plurality of output ports to be connected through the compound switch;

when the identified input port and the identified output port are connected to the same 1st-tier switch, issue a local command to that 1st-tier switch to effect a simple connection between the identified input port and the identified output port, or

when the identified input port and the identified output port are connected to different 1st-tier switches,

select a connection path from the identified input port to the identified output port through the 1st-tier switch connected to the identified input port, 1 selected 2nd-tier switch, and the 1st-tier switch connected to the identified output port, the connection path selected based, in part, on an expected insertion loss of the connection path, and

issue local commands to the 1st-tier switch connected to the identified input port, the selected 2nd-tier switch, and the 1st-tier switch connected to the identified output port to effect a compound connection along the selected connection path.

2. The compound optical circuit switch of claim 1, wherein the compound connection controller comprises:

an expected loss table storing an expected insertion loss for at least some of the possible connections between an input and an output of each of 1st-tier switches and each of the 2nd-tier switches.

3. The compound optical circuit switch of claim 2, wherein the compound connection controller is further configured to: select the connection path from the input port to the output port based, in part, on a insertion loss target included in the global connection command.

4. The compound optical circuit switch of claim 2, wherein the compound connection controller is further configured to:

20

select the connection path from the input port to the output port to equalize, to an extent possible, insertion losses of all compound connections.

5. The compound optical circuit switch of claim 4, wherein the compound connection controller is further configured to: select an available connection path having an insertion loss that is most nearly equal to an average expected insertion loss for all compound connections.

6. A method of making connection through a compound optical circuit switch including two or more 1st-tier switches and one or more 2nd-tier switches, the method comprising:

receiving a global connection command identifying an input port from a plurality of input ports and an output port from a plurality of output ports to be connected;

when the identified input port and the identified output port are connected to the same 1st-tier switch, making a simple connection within the 1st-tier switch; and

when the identified input port and the identified output port are connected to two different 1st-tier switches,

selecting a connection path from the input port to the output port through the 1st-tier switch connected to the identified input port, a selected 2nd-tier switch, and the 1st-tier switch connected to the identified output port, the selecting based, in part, on an expected insertion loss of the connection path, and

making a compound connection along the selected connection path.

7. The method of claim 6, further comprising:

when the identified input port and the identified output port are connected to the same 1st-tier switch, issuing a local command to that 1st-tier switch to effect the simple connection between the identified input port and the identified output port, or

when the identified input port and the identified output port are connected to different 1st-tier switches, issuing local commands to the 1st-tier switch connected to the identified input port, the selected 2nd-tier switch, and the 1st-tier switch connected to the identified output port to effect the compound connection.

8. The method of claim 6, further comprising:

storing an expected insertion loss for at least some of the possible connections between an input and an output of each of 1st-tier switches and each of the 2nd-tier switches in an expected loss table.

9. The method of claim 8, wherein selecting the connection path further comprises:

selecting the connection path from the input port to the output port based, in part, on an insertion loss target included in the global connection command and the expected loss table.

10. The method of claim 8, wherein selecting the connection path further comprises:

selecting the connection path from the input port to the output port based on the expected loss table to equalize, to extent possible, insertion losses of all compound connections.

11. The method of claim 10, wherein selecting the connection path further comprises:

selecting an available connection path having an insertion loss that is most nearly equal to an average expected insertion loss for all compound connections.
